Abstract: Satellite-based remote sensing technologies and Geographical Information Systems (GIS) present operable and cost-effective solutions for mapping fires and observing post-fire regeneration. Elwasita wildfire, which occurred during April and May in 2013 in Libya, was selected as a study site. This study aims to monitor vegetation recovery and investigate the relationship between vegetation recovery and topographic factors by using multi-temporal spectral indices together with topographical factors. Landsat 8 (OLI and TIRS) images from different data were obtained which were for four years; April 2013, June 2014, July 2015, and July 2016, to assess the related fire severity using the widely-used Normalized Burn Ratio (NBR). Normalized difference Vegetation Index (NDVI) was used to determine vegetation regeneration dynamics for four consecutive years. Also, the state of damage, vegetation recovery and, damage dimensions about the burned area were capable of being effectively detected using the result of supervised classification of Landsat satellite images. In addition, aspect, slope, and altitude images derived from Digital Elevation Model (DEM) were used to determine the fire severity of the study area. The results have found that it could be possible to figure out the degree of vegetation recovery by calculating the NDVI and NBR using Landsat 8 OLI and TIRS images. Analysis showed that it mainly oriented towards the north-west (47%), north (29%), and northeast (12%). The statistical analysis showed that fire was concentrated on the incline by 76%, and the most affected areas are those between 200 m-450 m above sea level, with a percentage of 80%. It is expected that the information can be acquired by various satellite data and digital forests. This study serves as a window to an understanding of the process of fire severity and vegetation recovery that is vital in wildfire management systems.

Keywords: GIS, NDVI, NBR, Satellite images.

INTRODUCTION

Fire is a natural factor that appears in all forest ecosystems and affects its numerous functions such as; adjusting plant succession and wildlife homeland, recycling nutrients, keeping biological diversity, decreasing biomass, and monitoring insect and disease populations. Therefore, fire can destroy trees and understory plants. Local species historically adjusted to fire and had a high regeneration capability. But since *Homo sapiens* first learned how to use fire, this balance was destroyed and the majority of forest fire has been of anthropogenic origin result-

ing in different tragic problems threatening the life of its main cause (Tishkov, 2004). The passive influences include air and water pollution, soil losses, destroyed biodiversity, desertification, soil corrosion, affecting human health and safety, as well as loss of human life. The Mediterranean basin is one of the world's biodiversity hotspots (Alacantara, 2010), where numerous civilizations over history relied on its forest resources for their cultural, economic, social, and esthetic service. However, every year fires damage millions of hectares of these surfaces (Maheras, 2002). This study serves as a window to an understanding of the process of fire

severity and vegetation recovery that is vital in wildfire management systems (Maheras, 2002). Fire is a considerable factor in the framework of many communities worldwide (Bond et al., 2005). There is an argument that fire was recurrent over the late Quaternary in the Mediterranean region (Carrion et al., 2003). Fires were recurrent much previously as many species have gained adaptive mechanisms to continue and regenerate after recurrent fires (Pausas & Verdú, 2005; Pausas, 2004). Mediterranean region biodiversity has been composition according to the various fire regimes. Therefore, it is obvious that in the Mediterranean region, fires are natural, they have happened for millennia, and plants can overcome them. In this case, fires ought not to be considered an ecological disaster but rather a part of the natural process. However, few studies suggest that current fire regimes may cause disasters in the sense of inducing sudden community changes or significant soil erosion (Arnan et al., 2007; Kazanis & Arianoutsou, 2004; Rodrigo et al., 2004).

Since the mid-eighties of the last century, numerous remote sensing applications have been preceding to assess fire severity on local and regional ecosystems. Some studies found fire caused vegetation shift measured by satellite sensors, whereas additional recent studies have discussed linking ecological measures to fire-induced physical changes on the land surface (Jakubauskas et al., 1990; White et al., 1996). When a plant is burned, a decrease in visible-to-near-infrared surface reflectance correlates with the charring and of vegetation (Eva & Lambin, 1998; Trigg & Flasse, 2000). At finer spatial resolutions, the burning of a large area of vegetation may, in some situations, lead to a rise in surface reflectance because of the deposition of white ash (Landmann, 2003; Roy & Landmann, 2005; Smith & Hudak, 2005; Smith et al., 2005). This is usually joined by an increase in the short wave infrared reflectance and brightness temperatures, which is imputed to the many effects of rising soil exposure, a rise in radiation absorption by charred vegeta-

tion, and reduced evapotranspiration comparative to the pre-fire green vegetation (Eva & Lambin, 1998; Smith et al., 2005; Stroppiana et al., 2002). The degree of post-fire change may vary depending on vegetation type, annual differences in growing season weather, and overall time since fire. For this reason, stratification among vegetation types, comparison of images with similar vegetation phenology, and image differencing techniques including pre-fire, immediate post-fire and 1-year-post-fire images have been recommended to assess fire effects and ecological change (Cocke et al., 2005; White et al., 1996). Moreover, canopy mortality, ground charring, and changes in soil color caused by fire; can be easily detected, provided sensors have an adequate spatial and spectral resolution (White et al., 1996).

Presently, remote sensing technology and GIS in the mapping and classification of natural resources are widely available. Using remote sensing to classify and analyze burned areas require some information on the land cover disturbance effect on the reflection of electromagnetic energy (White et al., 1996). After a dry season, and a severe shortage of rainfall and an increase of hot southern wind, fires erupted in Elwasita at north of Al-Bayda city in Al-Jabal Al-Akhdar region, during the months of April and May in 2013, which led to the destruction of vast areas of forest up to thousands of hectares (Masoud & Alajeel 2016).

The main objective of this study is to detect vegetation recovery following fire using Landsat 8 (OLI and TIRS) images and investigate the relationship between fire occurrences and topographic factors: altitude, slope, and aspect using GIS techniques. In this investigation, burn severity and vegetation recovery were assessed by using NDVI and NBR indices.

MATERIALS AND METHODS

Study Area: The Elwasita area is located in the Al-Jabal Al-Akhdar region on the northeast coast of Libya (Figure 1). Al-Jabal Al-Akhdar extends from a latitude of 32°00' to 33°00'N

and longitude of 20°00' to 23°00'E. With Libya's highest rainfall (600mm), the Al-Jabal Al-Akhdar region incorporates areas of intensive agriculture on plains and valley bottoms, and open woodland and shrubland on steep ravines and terra rosa slopes (Masoud, 2015).

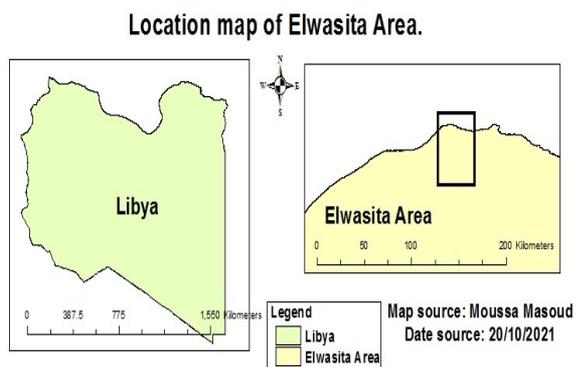

Figure: (1). Elwasita area in Al-Jabal Al-Akhdar, Libya.

Satellite imagery: A set of images Landsat 8 OLI and TIRS (with 11 spectral bands and 30 m spatial resolution) from different data, which were for four years from April in 2013 to July in 2016, were applied from Landsat 8 (OLI and TIRS) (<http://glovis.usgs.gov/>) to cover the entire study area, which is cloudless, enables simple processing and accurate classification (Table 1).

Table (1). List of Landsat Images

Satellite Images				
	Land- sat8(OLI and TIRS)	Land- sat8(OLI and TIRS)	Land- sat8(OLI and TIRS)	Land- sat8(OLI and TIRS)
Date	2013.04	2014.06	2015.07	2016.07

Each image has a spatial resolution of 30 meters, except for the panchromatic channel and the thermal-infrared bands, which have 15 and 100 meters resolution, respectively (Table 2).

Classification: Supervised classification was carried out for the years: April 2013, June 2014, July 2015, and July 2016. Ground control points, obtained using a Global Positioning System (GPS) from locations in relation to the classes of the study area, were plotted on Land sat 8 image, which was used to verify the training sites (defined classes) as regards the spectral signature. Supervised classification for the various classes was performed using finally maximum likelihood classification. For image classification, five classes were defined which are Burned area, Woodlands, Urban areas, Sea, Other uses.

Table (2). Landsat 8 band designations.

		Bands	Wavelength (micrometers)	Resolution (meters)
Landsat Operational Land (OLI) and Thermal Infrared Sensor (TIRS)	8 Imager	Band 1 - Coastal aerosol	0.43 - 0.45	30
		Band 2 - Blue	0.45 - 0.51	30
		Band 3 - Green	0.53 - 0.59	30
		Band 4 - Red	0.64 - 0.67	30
		Band 5 - Near Infrared (NIR)	0.85 - 0.88	30
		Band 6 - SWIR 1	1.57 - 1.65	30
		Band 7 - SWIR 2	2.11 - 2.29	30
		Band 8 - Panchromatic	0.50 - 0.68	15
		Band 9 - Cirrus	1.36 - 1.38	30
Launched February 11, 2013		Band 10 - Thermal Infrared (TIRS) 1	10.60 - 11.19	100
		Band 11 - Thermal Infrared (TIRS) 2	11.50 - 12.51	100

Assessment of Classification Results Using Error Matrix The error matrix-based accuracy assessment method is the most common and valuable method for the evaluation of change detection results. Thus, an error matrix and a Kappa analysis were used to assess change accuracy. Kappa analysis is a discrete multivariate technique used in accuracy assessments (Congalton & Mead, 1983; Jensen, 1996).

Normalized difference vegetation index (NDVI): NDVI is defined as the difference and ratio of reflection between visible ray and near-infrared wavelength. In this study, it was used to detect the change of vitality with the spatial distribution of vegetation, which is calculated using the following equation.

$$NDVI = (NIR - R) / (NIR + R) = (Band\ 5 - Band\ 4) / (Band\ 5 + Band\ 4).$$

Where:

NDVI – Normalized Difference Vegetation Index.

NIR – Near Infra-Red Band (band 5 Landsat 8 (OLI and TIRS)).

R – Red spectral band (visible, Red-band 4 Landsat 8 (OLI and TIRS)).

Normalized Burn Ratio (NBR): The formula is similar to NDVI, except that it uses near-infrared (NIR) and shortwave-infrared (SWIR) wavelengths. The NBR was designed to highlight burned areas and estimate fire severity, which is calculated using the following equation.

$$NBR = (NIR - SWIR) / (NIR + SWIR) = (Band\ 5 - Band\ 7) / (Band\ 5 + Band\ 7).$$

Where:

NBR – Normalized Burning Ratio.

NIR – Near Infra-Red Band (band 5 Landsat 8 (OLI and TIRS)).

SWIR – Short wave- Infrared band (band 7 Landsat 8 (OLI and TIRS)).

The Digital Elevation Model (DEM): The Digital Elevation Model (DEM) - SRTM-30m data was downloaded from the website (<http://www.diva-gis.org/gdata>). Altitude, slope, and aspect are among the most important data

in many natural resources. Elevation, slope, and aspect were derived from DEMs and used with other spatial data.

The digital image-processing software Envi5 was used for the processing, analysis, and integration of spatial data to reach the objectives of the study. The GIS software is used to assist planners in the analysis of such changes, by combining the maps derived from the classified images and integrating the multiple databases.

RESULTS

Classification: supervised classification of satellite images of April 2013, June 2014, July 2015, and July 2016 have shown clearly the amount of change in the land cover in the study area. For image classification, five classes were defined which are: Burned area, Woodlands, Urban areas, Sea, and, Other uses (Figure 2).

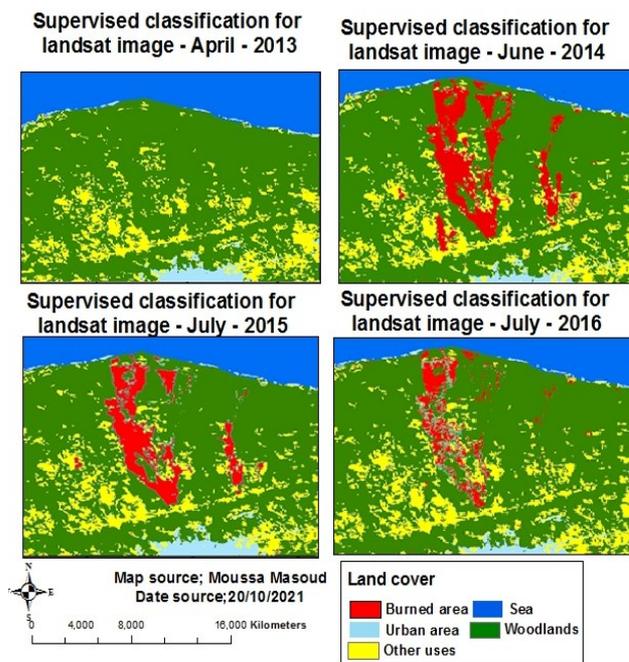

Figure: (2). Supervised classification of satellite images of Elwasita area in Al-Jabal Al-Akhdar for four years (April 2013, June 2014, July 2015, and July 2016).

The overall accuracy for the classified map based on the supervised classification was 90.3% which is considered good, and it is above the limit set by the USGS guidelines (85%). Because the overall accuracy assess-

ment tends to overestimate the actual performance, a more useful representation of performance is the Kappa coefficient (Cohen, 1960). The Kappa coefficient for the supervised image was 0.811, which means that 81.1% of the classification is better than a random classification.

This is considered good because a Kappa value above 80% is considered to have a strong agreement (Manandhar et al., 2009). Table 3 shows the results for the accuracy assessment for the supervised classification of the classified image.

Table(3). Matrixes of changes (Square Km) in land cover of classified map

	Sea	Urban Area	Other Uses	Woodlands	Burned Area	Total	Producer's Accuracy
Sea	24377	55	1232	0	0	25664	94.98519
Urban Area	0	520	45	110	2	677	76.80945
Woodlands		090.2	120	2409	5	2624.2	91.79941

Other Uses	728	4	21452	20	3	22207	96.60017
Total	25105	669.2	22854	2542	48.6	51218.8	
user's accuracy	97.10018	77.70472	93.86541	94.7679	79.42387		

Average accuracy 88.57
 Overall accuracy 90.3
 Overall Kappa statistics=0.811

NDVI: The interpretation implies the delimitation of the areas in tones of different colors, which shows characteristics of the vegetation. NDVI was calculated for all the satellite images (Figure 3).

NBR: One of the most widely used indexes for mapping burn severity is NBR, which combines the reflectance in the NIR and SWIR bands. NBR is a very sensitive index to emphasize burned areas and to determine the severity of the burns (Figure 4).

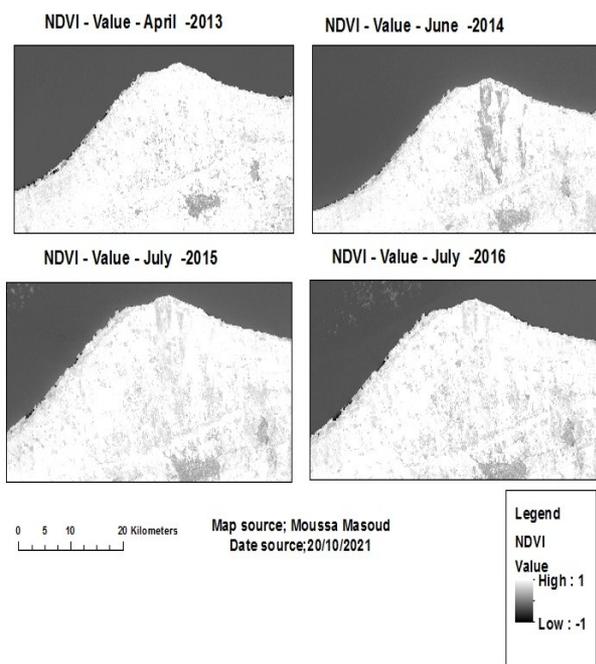

Figure: (3). Land covers change detection using NDVI.

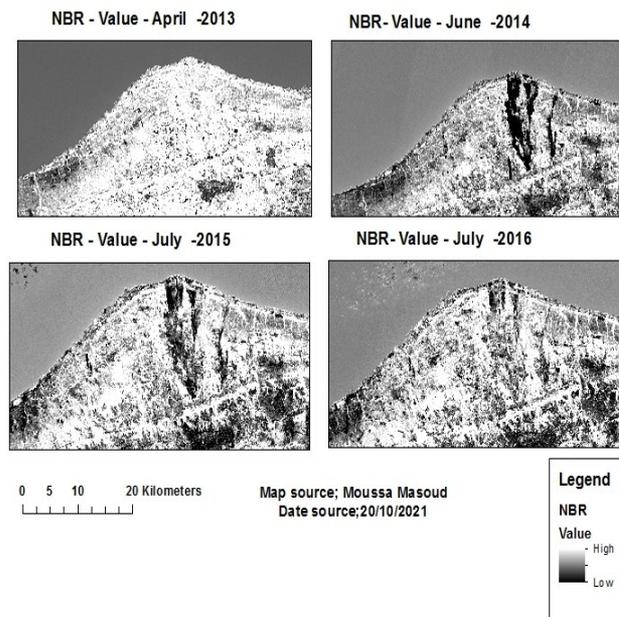

Figure: (4). Land covers change detection using NBR.

Slope: A slope is defined as the rate of change of elevation, expressed as a gradient in percentage or degrees. A slope map of the present

study area was prepared from DEM in GIS. The slope of the present study has been divided into three classes, which were slightly inclined, inclined, and strongly inclined (Figure 5). The statistical analysis showed that fire was concentrated on the inclined sections in a proportion of 76%, while 16 % in strongly inclined, and 8 % slightly inclined (Table 4). The results do not show any relationship between fires and slopes, but this may be due to the nature of the area exposed to fire and does not prove that there is no relationship.

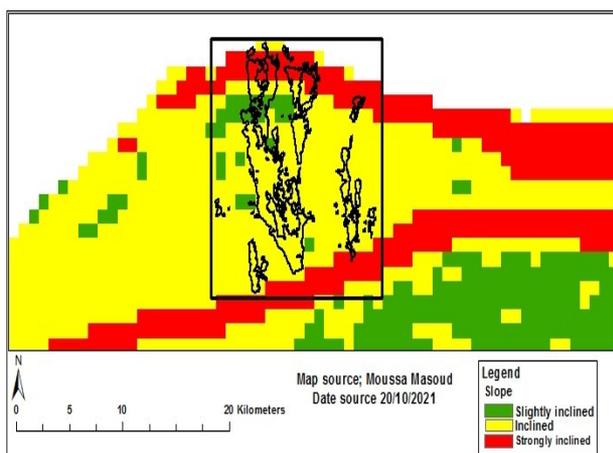

Figure (5). Map of the inclinations.

Table (4). Percentage of burned areas on the altitude, slope, and aspect.

Slightly inclined	8%	North West	47%	0-200m	20%
Inclined	76%	North	29%	200-450m	80%
Strongly inclined	16%	North East	12%	Above 450m	0%

Aspect: Aspect is the steepest downslope direction from each cell to its neighbors. It can be thought of as the direction of a slope or the compass direction a hill faces. According to a degree of a slope, its direction is categorized into nine classes (Figure 6). The results have found they mainly oriented towards NW (47%), N (29%), and NE (12%) slope orientation (Table 4). The results found that the areas most exposed to fire are the northeastern aspect, followed by the northern aspect.

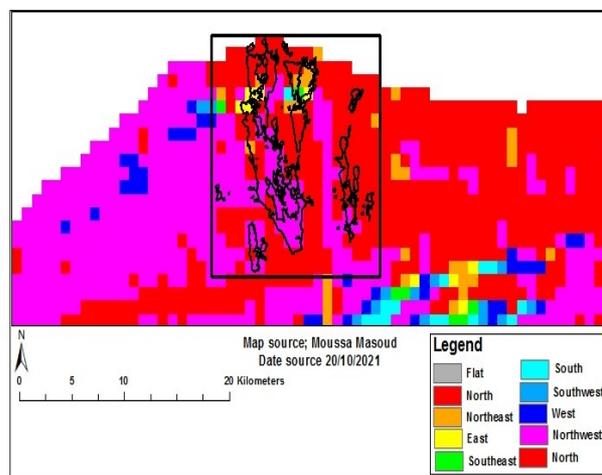

Figure (6). Map of slopes exposure.

Altitude: Another element with an important role in analyzing forest fire is altitude; because it determines the accessibility of affected areas for intervention, and high areas have a low degree of accessibility. In more detail, the altitude of the affected areas as defined in 3 classes are; between sea level to 864 meters (sea level to 200 m, 201-450, and 451- 864) (Figure 7). Thus it was observed that the most affected areas were those between 200 m-450 m, with a percentage of 80%. Also affected were the classes from sea level to 200 m in a proportion of 20%, while the area between 451 - 864 m was free of fire (Table 4).

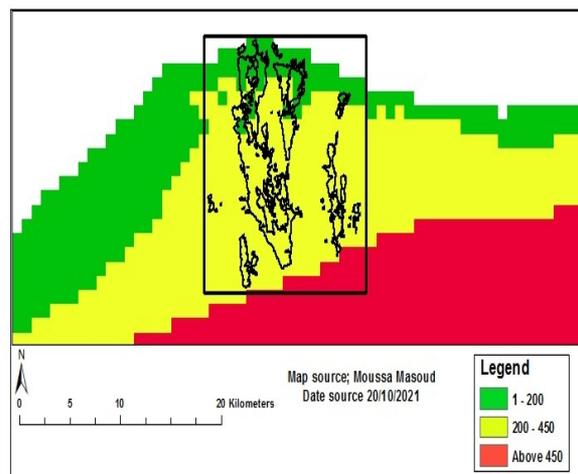

Figure (7). Altitude map of the three categories.

DISCUSSION

Post-fire monitoring in the Elwasita area was achieved using supervised classifications, NDVI, and NBR. The results explain how remote sensing can be applied to estimate, observe, and quantify post-fire in a massive zone where traditional procedures (such as field observation) may not be possible.

In this study, land cover classification images for four years (2013, 2014, 2015, and 2016) were carried out. The results have found that burned areas decreased. On the other hand, the woodland area increased. This indicates the natural recovery of woodlands with time. Especially it was concluded that the amount of recovery increased significantly from 2013 to 2016 (Figure2).

Numerous studies found that the NBR is the most effective index for burn severity. The NBR is estimated as the difference between near-infrared (NIR) and short-wave infrared (SWIR) reflectance divided by their sum (Key & Benson, 2005). The NDVI is another widely utilized index that is an indicator of plant greenness, measuring plant type, and amount on land surfaces. Many studies have used NDVI to monitor post-fire vegetation dynamics in the Mediterranean region (Mitri & Gitas, 2010; Petropoulos et al., 2014; Veraverbeke et al., 2010).

The results have shown NDVI images are the most useful to quantify the difference in photosynthetically active vegetation. Not only can a distinct presence and absence within the perimeter be determined by looking at the images, but it is also easy to generate charts using the information provided by the image. Figure 3 shows the difference in the average NDVI values in the two subsets; burned and unburned area for four years. The highest values of NDVI (0.75 - 2013, 0.51 - 2014, 0.63 -2015, 0.72-2016) are correspondent to the tones of white and reach up to 1. These are associated with the thickest and healthiest forests. The darkest tones, close to black, show the exact opposite of what was mentioned above. The

lack of vegetation, chlorophyll, is expressed by the bare soil or rock, which absorb the near-infrared more.

NDVI has been confirmed to be specifically sufficient to estimate post-fire recovery of Mediterranean ecosystems (Díaz-Delgado et al., 1998; Fox et al., 2008; Gouveia et al., 2010; Hope et al., 2007) as well as to observe vegetation dynamics subject to stress conditions such as those associated to major drought situations (Gouveia et al., 2009). Some authors (Epting & Verbyla, 2005; Kokaly et al., 2007; Miller et al., 2009; Miller & Thode, 2007) have successfully estimated burn severity established on temporal changes between pre and post-fire satellite imagery, namely by using differences of pre-and-post-fire NDVI values (De Santis & Chuvieco, 2007; Fox et al., 2008).

The NBR index displayed itself to be more critical to the pre-/post-fire displacements of the pixels influenced by the fire in the MIR-NIR space than the NDVI in the R-NIR space. Healthy vegetation shows a very high reflectance in the NIR, and low reflectance in the SWIR portion of the spectrum. The opposite of what is seen in areas devastated by fire. Both indices were hardly sensitive to the pre-/post-fire spectral changes corresponding to the unaffected pixels attributable to “perturbing factors”. The pre-/post-fire indices are the most appropriate ones for holding out the discrimination between pixels not burned by a fire and pixels affected by a fire. The results showed that there was a slight difference in the vegetation recovery rate measured by the NBR between the different years with NDVI.

Furthermore, it is worth noting the greater capacity of the NBR to determine fire severity levels, which is in agreement with the results of previous works that compare NBR and NDVI (Pereira, 1999). The effective use of altitude information can detect physical conditions on the land that may increase or decrease a property's risk of natural hazards (Figure 7). It is observed that the most affected areas are those

between 200 m-450 m, with a burned area percentage of 80%. Also, a visual interpretation of the relationships between woodlands recovery and topography are presented in Figures 5, 6, and 7 respectively. Comparing the two index results, it can be seen that stronger recovery dynamics appeared to occur in the northwest and north of the burn area. It is common with other studies and many authors; finding that recovery was better on north-facing slopes compared to south-facing slopes related to northern hemisphere dynamics (Fox et al., 2008). This fact reveals that vegetation recovery dynamics following a forest fire event take a long time.

This study was aimed towards showing that remote sensing is a helpful management tool and that quantifiable data could be taken from the images using basic image enhancements and simple band math. Demonstrating that a land manager could manipulate images and can monitor landscape level changes. By using remotely sensed imagery in a more common pattern, managers could keep resources by performing small field studies to get precise data on the rate of change. Remote sensing has been perceived to be a robust tool to observe post-fire vegetation recovery over different regions (Epting & Verbyla, 2005; Goetz et al., 2006) that include Mediterranean ecosystems (Minchella et al., 2009; Röder et al., 2008). The method established on remote sensing has also been successfully utilized to evaluate fire risk (Chuvieco et al., 2010), burn severity (De Santis & Chuvieco, 2007; Epting & Verbyla, 2005; Fox et al., 2008; Kokaly et al., 2007; Miller et al., 2009; Miller & Thode, 2007) and erosion risk (Fox et al., 2008).

Future studies in this area should include using more study areas with different types of and vegetation to accurately display the extent to which NDVI and NBR can be used. Another suggestion would be to study the meteorological indicator effect to enclose the entire perimeter of the fire using remote sensing and GIS.

CONCLUSION

NDVI, NBR, supervised classification, aspect, slope, and altitude images were used to determine the fire severity and vegetation recovery of the study area. Analysis showed that it mainly oriented towards the northwest (47%), north (29%), and northeast (12%). The statistical analysis showed that fire was concentrated on the inclined in a proportion of 76%, and the most affected areas are those between 200 m-450 m above sea level, with a percentage of 80%.

المستخلص: تقنيات الاستشعار عن بعد المعتمدة على الأقمار الصناعية، وأنظمة المعلومات الجغرافية (GIS) تقدم حلولاً قابلة للتشغيل، وفعالة من حيث التكلفة لرسم خرائط الحرائق، ومراقبة التجدد بعد الحرائق. تم اختيار حريق الوسيطة، الذي حدث خلال شهري أبريل ومايو في عام 2013 في ليبيا، موقعا للدراسة. تهدف هذه الدراسة إلى مراقبة استعادة الغطاء النباتي، والتحقق في العلاقة بين استعادة الغطاء النباتي، والعوامل الطبوغرافية باستخدام المؤشرات الطيفية المتعددة مع بعض العوامل الطبوغرافية. تم الحصول على صور فضائية للقمر الصناعي Landsat 8 (OLI و TIRS) من بيانات مختلفة، والتي كانت أربع سنوات من أبريل 2013، يونيو 2014، يوليو 2015، و يوليو 2016، لتقييم شدة الحريق باستخدام نسبة الحرق الطبيعي المستخدمة على نطاق واسع (NBR). تم استخدام دليل الاختلاف للغطاء النباتي (NDVI) لتحديد ديناميكيات تجدد الغطاء النباتي لمدة أربع سنوات متتالية. تم استخدام التصنيف المراقب بنجاح لتحديد المنطقة التي تعرضت للحريق، ومقدار التجدد الطبيعي بعد ذلك. بالإضافة إلى ذلك، تم استخدام كلا من الارتفاع، والانحدار، والجوانب المستمدة من نموذج الارتفاع الرقمي (DEM) لتحديد شدة الحريق في منطقة الدراسة. وجدت النتائج أنه يمكن معرفة درجة التجدد الغطاء النباتي عن طريق حساب NDVI، و NBR باستخدام صور Landsat 8 OLI, TIRS. أظهر التحليل أنه موجه بشكل رئيسي نحو الشمال الغربي (47%)، الشمال (29%)، والشمال الشرقي (12%). وأظهر التحليل الإحصائي أن الحريق تركز على منحدر بنسبة 76%، وأكثر المناطق تضررا هي تلك التي تتراوح بين 200 م، و 450 م فوق سطح البحر، وبنسبة 80%. من المتوقع أن يتم الحصول على المعلومات من خلال بيانات الأقمار الصناعية المختلفة، والغابات الرقمية. تعمل هذه الدراسة كنافذة لفهم عملية شدة الحرائق، واستعادة الغطاء النباتي الذي يعد أمراً حيوياً في أنظمة إدارة حرائق الغابات.

الكلمات المفتاحية: نظم المعلومات الجغرافية، دليل الاختلاف للغطاء النباتي، نسبة الحرق الطبيعي، صور الأقمار الصناعية.
